### ABSTRACT

The metallurgical basis for high damping in Fe-Cr-based alloys was investigated. Two alloys similar to VACROSIL-010 were studied, with compositions of 84.7 Fe-11.44 Cr-2.91 Al and 84.8 Fe-11.65 Cr-2.92 Mo. The strain dependence of specific damping capacity (SDC) was evaluated using a modified version of the resonant dwell technique. Heat treatment variations were introduced by annealing in argon gas at temperatures between 950°C and 1100°C and then furnace cooling. Cantilever beam specimens were evaluated for SDC at their first three resonant modes (0-1,000 Hz) at room temperature. Changes in damping capacity were correlated with the results of tensile hysteresis testing and dilatometry.

## ACKNOWLEDGMENTS

The author wishes to extend his appreciation to his advisor Professor Jeff Perkins for his guidance and organization. Electronics Technician Tom Christian and Material Science Laboratory Technicians Tom Kellogg and Tommy Bloomer were invaluable in setting up the new lab, and were tireless in their instruction in using the new equipment.

A special note also to Mechanical Engineering Laboratory Manager Tom McCord for the excellent machine work on test samples and for his efforts in installing new facilities.

And I am deeply indebted to my wife, Gail, for her patience.

## I. INTRODUCTION

### A. GENERAL

The U.S. Navy is currently investigating the reduction of noise and vibration in both submarine and surface ship design. For both platforms it is desirable to remain quieter than ambient noise to minimize detection. It is also important to minimize noise interference with one's own sensors. Noise reduction may also improve component fatigue life and reduce hazards to personnel due to high ambient noise levels.

Schetky and Perkins [Ref. 1] list three primary methods of reducing noise and vibration:

1. Isolation of the sources (moving parts) and the surrounding surfaces that can radiate energy.
2. Dissipation of the energy transmitted through the structure, using isolation pads.
3. Construction of structural or machine components themselves from energy absorbing structural materials. These high damping materials would serve the dual purposes of structural support and noise abatement.

The problems inherent in the first two methods are that resilient mounts, hangers, and encapsulating shrouds take up space, add weight, and increase the complexity of maintaining the system. Method three can eliminate these problems, but design with high damping materials is an uncertain and potentially difficult matter at present. For one thing, the mechanisms of damping are not well

understood, and the influence of important factors such as temperature, strain, heat treatment, and deformation are incompletely characterized.

The U.S. Navy is currently quite interested in investigating the damping properties of commercial high damping alloys, including correlations between the relevant microstructural and physical properties.

## B. OBJECTIVES

High damping alloys have been investigated for over 40 years, yet information on the damping properties of Fe-Cr and other ferromagnetic high damping alloys is relatively limited [Ref. 2]. A new alloy has been introduced commercially by Vacuumschmelze, G.M.B.H. (VAC), of Hanau, West Germany. This alloy has the registered trade name of VACROSIL-010, with two diverse compositions, Fe-Cr-Al and Fe-Cr-Mo (this latter a corrosion-resistant grade) [Ref. 3]. The alloys used in this study were not VACROSIL per se (i.e., were not supplied by Vacuumschmelze, G.M.B.H.), but rather were "clones" of the two alloy versions. These two versions of the alloy will be referred to in this report as "Fe-Cr-Al" and "Fe-Cr-Mo." The corrosion resistant version is of particular interest for marine applications.

The purpose of this research is to continue to explore the damping characteristics of these alloys from a metallurgical point of view. The following objectives guided this research:

1. To assemble a damping test apparatus and develop standard, reproducible test procedures.
2. To determine the effect of heat treatment on the relationship between applied strain and damping capacity under random vibration conditions.
3. To analyze and compare the physical properties of the Fe-Cr-Al and Fe-Cr-Mo alloys.
4. To attempt to correlate the damping capacity with phase changes using a dilatometer.
5. To investigate possible pseudoelastic effects at low levels during tensile loading.

### C. BACKGROUND

All materials exhibit an ability to dampen the propagation of energy. However, in most metals the damping capacity is quite low, on the order of 1% to 10%. Recently, alloys have been developed with damping capacities well in excess of 10%. These high damping ("quiet metal") alloys show good potential for use in noise and vibration control applications.

These alloys include Mn-Cu-based alloys; ferromagnetic alloys from the Fe-Cr, Fe-Co, and Co-Ni system; and shape memory alloys from the Ti-Ni, Cu-Zn-Al, and Cu-Al-Ni systems. Research on these systems has led to the introduction of various commercial alloys for high damping applications. From the Mn-Cu system has come the alloys called "INCRAMUTE" (International Copper Research Association) and "SONOSTON" (British Stone Marine Manganese Ltd.). SONOSTON has been used for ships propellers in

Europe while INCRAMUTE has been used for noise reduction in tools and machinery.

Several ferromagnetic alloys have been introduced commercially, including "SILENTALLOY" (Toshiba Co.), "TRANQUALLOY" (Nippon Steel Co.), "VACROSIL" (Vacuumschmelzer G.M.B.H.), and "NIVCO" (Westinghouse). These alloys show promise for vibration control in automobiles and electrical machinery.

Recent research at the Naval Postgraduate School has included work on SONOSTON [Refs. 4,5], INCRAMUTE [Refs. 2,5], and a VACROSIL-type alloy [Ref. 6]. This study continues the investigation of VACROSIL-type alloys.

The damping mechanism for the Fe-Cr-based alloys has been shown to be based primarily on the ferromagnetic properties of the alloy [Refs 3,7-14]. In particular, de Batiste [Ref. 8] states that the damping is related to the interaction of the applied stress field and the domain boundaries. He also relates the effects of varying parameters such as temperature, amplitude, frequency and field strength on damping capacity.

The present research investigates the effects of heat treatment and strain on damping of two Fe-Cr-based alloys.

## D. DAMPING MECHANISMS

### 1. Macrostructural Damping

#### a. Parameters

The dissipation of energy by a material is known as damping. The energy loss per cycle divided by the peak potential energy is defined as the specific damping capacity (SDC) [Ref. 15:p. 70]. Several parameters are used to describe vibration damping.

(1) General Equation. For a simple model of a linear system with one degree of freedom and viscous damping, the general differential equation is of the form [Ref. 15:p. 25]:

$$m\ddot{x} + c\dot{x} + kx = F \quad (1.1)$$

where:

$m$  = mass

$c$  = viscous damping coefficient

$k$  = spring constant

$F$  = excitation

$x$  = displacement

$\dot{x}$  and  $\ddot{x}$  = the first and second derivatives of displacement with respect to time.

#### (2) Natural Frequency ( $\omega_n$ ).

$$\omega_n = (k/m)^{1/2} \quad (1.2)$$

The mode 1 resonant frequency is called the natural frequency. The characteristic response for the first three modes is shown in Figure 1.1.

(3) Critical Damping Factor ( $C_c$ ) [Ref. 15:p. 27].

$$C_c = 2m\omega_n \quad (1.3)$$

(4) Damping Ratio of ( $\zeta$ ) [Ref. 15:p. 27].

$$\zeta = c/C_c \quad (1.4)$$

If the excitation ( $F$ ) is represented in the complex form ( $Fi\omega t$ ) and  $c = 2m\omega_n\zeta$ , then the steady state solution to Equation 1.1 is of the form [Ref. 16:p. 130]:

$$x = Xe^{i(\omega t - \phi)} = Fi\omega t / [(k - m\omega^2) + i\omega c] \quad (1.5)$$

(5) Logarithmic Decrement ( $\delta$ ).

$$\delta = \ln(a_i/a_{i+1}) \quad (1.6)$$

The logarithmic decrement is defined as the natural logarithm of the ratio of any two successive amplitudes of vibration. Greater accuracy can be obtained if the ratio of two amplitudes  $n$  cycles apart is used [Ref. 17:p. 68]. The logarithmic decrement is now expressed as:

MODE 1

MODE 2

MODE 3

Figure 1.1 Characteristic Response of Cantilever Beam to First Three Modes of Excitation

$$\delta = 1/n \ln(a_i/a_{i+n}) \quad (1.7)$$

(6) Normalized Bandwidth.

$$\text{Normalized bandwidth} = (\omega_2 - \omega_1) / \omega_n \quad (1.8)$$

The normalized bandwidth is the width of the resonant peak at 0.707 ( $\sqrt{2}/2$ ) times the peak amplitude normalized by its associated resonant frequency (Figure 1.2). The stored energy is half its maximum value at this point.

(7) Internal Friction ( $Q^{-1}$ ).

$$Q^{-1} = (\omega_2 - \omega_1) / \omega_n = 2\zeta \quad (1.9)$$

The normalized bandwidth is also known as the internal friction. It is analogous to the damping or energy loss in an electrical system [Ref. 18:p. 445].

(8) Quality Factor ( $Q$ ).

$$Q = \omega_n / (\omega_2 - \omega_1) \quad (1.10)$$

The quality factor is the inverse of the normalized bandwidth. It is a measure of the sharpness of the resonant peak [Ref. 15:p. 76].

Figure 1.2 Normalized Bandwidth

(9) Phase Angle ( $\alpha$ ).

$$\tan \alpha = (1/\pi) \ln(a_i/a_{i+1}) \quad (1.11)$$

The phase angle is the angle by which the strain lags behind the stress in cyclic loading. The tangent of the phase angle can be taken as an index of energy loss [Ref. 15:p. 495]. If damping is small, i.e., ( $\zeta \ll 0.5$ ), then,

$$\tan \alpha = \delta / \pi = Q^{-1} = 2 \zeta \quad (1.12)$$

(10) Specific Damping Capacity (SDC) [Ref. 18:p. 444].

$$SDC = (a_{i+1}^2 - a_i^2) / a_i^2 \quad (1.13)$$

Again if ( $\zeta \ll 0.5$ ), then

$$SDC(\%) = 200 \pi Q^{-1} \quad (1.14)$$

(11). Resonant Frequency ( $\omega_n$ ).

$$\omega_n = (\beta_n l)^2 (EI/ml^4)^{1/2} \quad (1.15)$$

This is the natural frequency of the  $n^{\text{th}}$  mode of a cantilever beam [Ref. 15:p. 464], where:

$E$  = Young's Modulus of Elasticity  
 $I$  = moment of Inertia  
 $m$  = mass density per unit length  
 $l$  = vibrating length of the beam  
 $\beta_n l$  = values for several vibration modes (n) for a clamped-free beam. [Ref. 15:p. 466]

$n$	$\beta_n l$	$(\beta_n l)$
1	1.8751	3.5160
2	4.6941	22.0345
3	7.8548	61.6972

#### b. Measurement Method

Damping measurements in Fe-Cr-based alloys have been made with an inverted pendulum apparatus or a cantilever beam; usually under free decay conditions [Refs. 9-11,19]. A cantilever beam method was developed by Bolt, Beranek, and Newman, Inc., known as the single cantilever beam resonant dwell method [Ref. 20]. It is used to determine stress and frequency dependence of material damping over a frequency range of 25-1,000 Hz. The method indirectly determines the loss factors of simple structural elements by measuring their response to excitation at modal frequency.

In this method, the simple structural element is a thin section cantilever beam clamped to a weighted bar. The bar is connected to a random vibration generator at one

end and a heavy support frame at the other. The vibration input is measured by an accelerometer on the clamp at the base of the sample. The system tip deflection (response) is measured by a microscope focused on the tip of the beam. The beam tip is illuminated by a stroboscope.

This method was modified by Professor Y.S. Shin of the Naval Postgraduate School, wherein the system response is measured by an accelerometer at the beam tip. The signals of the input and output accelerometers are compared by a spectrum analyzer to produce the system transfer function. Strain response of the beam is measured by a strain gage placed at the first nodal point of the beam. A sample specimen is illustrated in Figure 1.3.

## 2. Microstructural Damping

The microstructural effects and interactions within a material result in damping. The phenomena associated with high damping in cyclically stressed crystalline materials are:

- a) dislocation damping
- b) interphase boundary damping
- c) phase change effects.

The primary mechanism of damping in ferromagnetic materials is the magneto-mechanical hysteresis effect, a type of interphase boundary damping, described by de Batiste [Ref. 8]. The application of a mechanical or magnetic stress causes the domains which are favorably aligned to the stress

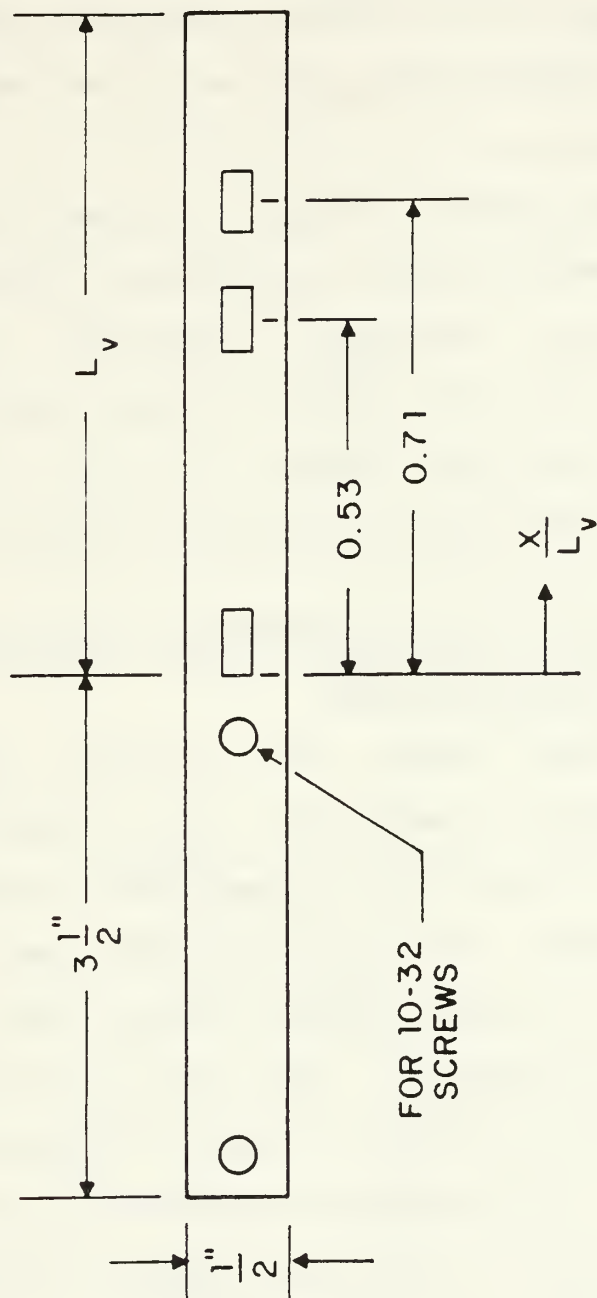

Figure 1.3 Specifications for Resonant Dwell Method Damping Specimens

to grow preferentially to those domains not so favorably aligned. An increase in stress may cause a rotation of the magnetic moment vector within the domains toward the stress direction. Both effects increase the net magnetic moment of the sample [Ref. 18].

If the stress is supplied by an external force, the energy is used to rotate the domains. Therefore it is not all transmitted, resulting in damping. Prestressing the sample may result in larger aligned domains that do not rotate under the given stress, in which case less external energy may be absorbed and damping is decreased.

#### E. METALLURGY OF THE IRON-CHROMIUM ALLOY SYSTEM

##### 1. Physical Properties

Stainless steels are divided into three main classes: ferritic, austenitic, and martensitic. The high damping Fe-Cr-based alloys are closely related to ferritic stainless steels. Ferritic stainless steel consists of an Fe-Cr alpha ( $\alpha$ ) solid solution with a body centered cubic (bcc) crystal structure. The alloy contains very little dissolved carbon, mostly as finely divided chromium carbide precipitates. The chromium content varies from about 12 to 30 weight percent. The alloy remains ferritic (bcc) up to the melting point [Ref. 21:p. 5-2].

The binary Fe-Cr phase diagram (Figure 1.4) shows a so-called gamma ( $\gamma$ ) loop extending from about 0 to 12% chromium and temperatures from 850°C to 1400°C.

Figure 1.4 Fe-Cr Binary Phase Diagram

Figure 1.5 The Gamma Loop of the Fe-Cr Phase Diagram

When the alloy coordinates are moved to within the gamma loop the alloy undergoes a phase change to the face centered cubic (fcc) form. An expanded view of the gamma loop is shown in Figure 1.5. The gamma loop is separated from the alpha region by a narrow two-phase band. The size, shape, and extent of the gamma loop can vary considerably with the proportions of ferritic stabilizing elements (such as chromium) and austenitic alloying elements (such as carbon and nitrogen) [Ref. 21:p. 5-2].

A three-component phase diagram for Fe-Cr-Mo is shown in Figure 1.6. Here we may notice that several intermetallic phases are possible. The most significant of these is the chi ( $\chi$ ) phase; a cubic structure of approximate composition  $\text{Fe}_{36}\text{Cr}_{12}\text{Mo}_{10}$  or  $\text{Fe}_3\text{CrMo}$  [Ref. 22].

Some disadvantages of ferritic stainless steels are their poor machinability, poor weldability, high notch sensitivity and their susceptibility to embrittlement. The advantages of ferritic stainless steels include good damping properties and good corrosion resistance. Some of the corrosion resistance and ductility are lost after exposure to high temperatures, but this can be alleviated somewhat by alloying with molybdenum.

## 2. Damping Properties

The primary mechanism of damping in ferromagnetic alloys is associated with magneto-mechanical hysteresis

Figure 1.6 Ternary Phase Diagram for Fe-Cr-Mo  
(a) 900°C Isotherm and (b) 1250°C Isotherm

(domain boundary) damping. In this, the inhibition of motion of the domain walls is the determinant of damping capacity and factors that affect the domain wall mobility will directly affect the damping capacity.

A temperature increase reduces magnetic permeability. Heating above the critical (Curie) temperature results in a random orientation of the domain boundaries and a transformation of the material from ferromagnetic to paramagnetic. This was originally considered to be a beta ( $\beta$ ) phase of iron, but since the structure remains body centered cubic throughout this range, it is now considered a transformation within the alpha ( $\alpha$ ) phase [Ref. 18:p. 455].

The amplitude of applied strain also affects the damping capacity, causing an increase to a maximum value. Beyond that value, increasing stress will cause a decrease in damping.

Residual stresses that block domain mobility will tend to adversely affect damping capacity. Schneider, et al. [Ref. 12], report that, "damping capacity is strongly deteriorated by cold work. A reduction of  $\geq 5\%$  completely destroys the damping effect; however, it can be fully restored by a succeeding heat treatment."

Magnetic fields cause preferential growth of the domain walls along the line of the applied field. The domain walls become progressively less mobile with

increasing field strength and the damping capacity of the material is correspondingly reduced. Damping capacity disappears at magnetic saturation at about 100 A/cm [Ref. 12].

## II. EXPERIMENTAL PROCEDURE

The David W. Taylor Naval Ship R&D Center (NSRDC), Annapolis, Maryland supplied partial ingots from two different Fe-Cr-based alloys. The ingot sections as provided were approximately 12.75 in. x 3.5 in. x 1.625 in. Bulk analysis, supplied with the ingots, was performed by Luvak Inc. of Boyleston, Ma. (Report number 0-1500): Their findings are presented in Table 1.

Dilatometer samples were machined from the ingots in accordance with Reference 23, Section IV. The tests were conducted on an Orton Automatic Recording Dilatometer Model 15 BC-1. All tests were performed in a flowing argon gas atmosphere.

Tensile specimens were machined from the ingots as per Reference 24. The tests were performed on an Instron Universal Testing Instrument Model TT-D. Specimens were tested to fracture directly or were subject to cyclic loading. The load on the cyclic samples was increased in steps until plastic deformation occurred. Then the samples were pulled to fracture. All samples were tested at room temperature at strain rates of  $0.641 \times 10^{-3} \text{ sec}^{-1}$ .

Damping specimens were machined to the specifications of the modified Resonant dwell technique [Ref. 20]. Strain

gages were attached at the three model points (Figure 1.3). Specimen dimensions are listed in Table 2.

The various specimens were annealed for one hour in a Lindberg Hevi-Duty Type 54253 tube furnace, at temperatures of 950°C, 1000°C, 1050°C, and 1100°C. All specimens were annealed and furnace cooled under flowing argon gas. The samples were stored at room temperature.

A new testing apparatus was developed and used for the damping capacity measurements. This apparatus was based on a Spectral Dynamics SD-380 Signal Analyzer providing a 40 kHz broadband noise signal to an MB Dynamics Inc. Model 2125MB amplifier which then drove an MB Dynamics Inc. Model PM-25 Vibration Exciter. The PM-25 oscillated an instrumented cantilever beam specimen. One end of the beam was free and one was clamped. Acceleration of the beam base and tip were provided to the SD-380 Signal Analyzer by two Endevco Model 2250A-10 accelerometers via Endevco Model 4416A signal conditioners.

Strain measurement was provided to the SD-380 Signal Analyzer by Measurements Group Inc. strain gages (model CEA-13-250UN-350) via a Measurement Group Inc. bridge amplifier meter (BAM-1). The BAM-1 and the SD-380 were calibrated to give a direct reading of microstrains.

The interference to mode one excitation low strain frequency response reported in References 2 and 6 was also

noticed here. The amplifier as well as the shaker may be contributing to this.

A block diagram of the system is given in Figure 2.1.

In some of the following figures reference is made to test specimens by their local designations which are as follows:

The first letter indicates the material; A--aluminum (Fe-Cr-Al) or M--molybdenum (Fe-Cr-Mo).

The second letter indicates the sample usage; T--tensile specimen, D--dilatometer sample, B--SDC beam, etc.

The number in the third position is the number of the sample. For example: AT-4 is the fourth tensile sample of Fe-Cr-Al, and MB-2 is the second SDC beam of Fe-Cr-Mo.

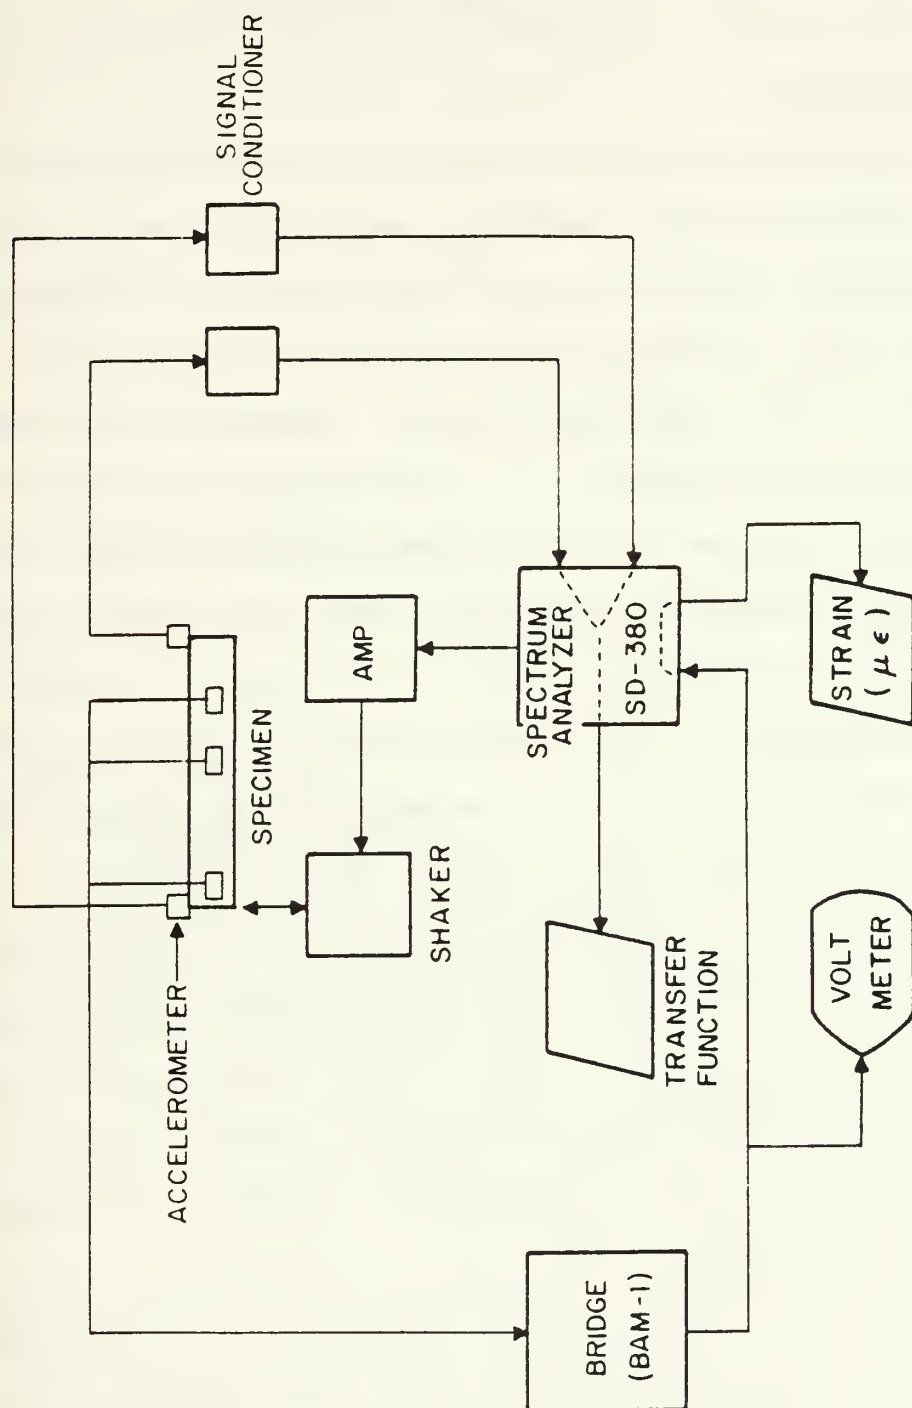

Figure 2.1 Damping Capacity Testing Block Diagram

### III. RESULTS AND DISCUSSION

#### A. DILATOMETRY

In a previous study of an Fe-Cr-Mo alloy by O-Toole, an unusual variation in damping properties for a 1000°C anneal/furnace cooled specimen was noticed when compared to the same alloy when annealed at other temperatures. In particular, SDC was less than expected and tensile properties were higher. It was postulated that the difference might be due to a phase change taking place, perhaps related to an interaction with the gamma loop (see the Fe-Cr phase diagrams, Figures 1.4, 1.5) or perhaps due to the intermetallic chi phase (see the ternary Fe-Cr-Mo diagram, Figure 1.6). Optical examination by O'Toole showed what could be some slight second phase formation at the grain boundaries of furnace cooled specimens (absent in water-quenched specimens). This second phase was assumed to be the chi ( $\chi$ ) phase. However, no direct correlation between this sort of microstructure and damping capacity was determined, and O'Toole recommended further investigation, such as via dilatometry [Ref. 6].

Dilatometric investigation in the present work showed a slight change in slope at about 750°C, but certainly not the characteristic "notch" in the length vs. temperature plot which would indicate a distinct phase change. A typical

dilatometric plot (for the Fe-Cr-Al alloy) is shown in Figure 3.1. A similar slope change is seen for the Fe-Cr-Mo sample (Figure 3.2). For comparison purposes, the plot for a sample of pure iron is presented in Figure 3.3, wherein an obvious phase change occurs in the vicinity of 910°C, as predicted in the equilibrium phase diagram (Figure 1.4).

Various dilatometric scans were performed with variations in the following parameters: heat treatment, heating rate, cooling rate and soaking time at maximum and intermediate temperatures. In all cases the results closely followed those illustrated, with no distinct evidence of a phase change over the temperature range scanned (18°C-1100°C).

## B. TENSILE TESTING

### 1. Tests to Fracture

The method of tensile testing to failure used by O'Toole [Ref. 6] was modified to accommodate the tendency of these rather large-grained Fe-Cr-based alloys to fail to break cleanly under load. The large-grained samples tend to develop a mottled, dimpled appearance at the onset of necking, and further loading typically produces longitudinal cracks. These cracks separate into individual longitudinal strands with a cable-like appearance, and the individual strands then break in sequence. The resultant stress strain curves show a long slow decline after necking punctuated by vertical dips as each strand breaks, and the

Figure 3.1 Fe-Cr-Al Dilatometry

Figure 3.2 Fe-Cr-Mo Dilatometry

Figure 3.3 Iron Dilatometry

stress level nearly reaches zero before the final strand parts.

In order to eliminate the maximum elongation error due to these effects, the final fracture point on all curves was arbitrarily taken to be at a strain (beyond necking) corresponding to 0.75 times the ultimate tensile strength (UTS). The resulting stress-strain curves are presented in Figures 3.4, 3.5, and 3.6 and the strength vs. ductility data are presented in Table 3. Ductility was measured by taking 100 times the charted strain distance (the distance from the tangent to the elastic slope of the curve to the point of 0.75 times the tensile strength less the elastic portion of the curve) divided by the magnification factor (the chart speed divided by the cross-head speed) times the gage length.

$$\frac{e_{cf}}{\text{mag} \cdot l_o} \times 100 = \text{Ductility} \quad (3.1)$$

As a comparison another measure of ductility, the percent elongation, was calculated using the standard gage length formula.

$$\frac{l_F - l_o}{l_o} \times 100 = \% \text{ elongation} \quad (3.2)$$

As can be seen in Table 3, these methods agree quite closely for the aluminum samples, but not as well for molybdenum samples.

1000	32.05	44.02	16.19	25.38

Of great interest was the elastic nonlinearity reported previously by O'Toole [Ref. 6]. This was noticed again in the present work and will be discussed in more detail later. However, for the purposes of simply showing the basic strength and ductility mechanical properties, the nonlinear portions of the curves, at low stress, have been omitted in the presentation of Figures 3.4-3.6. Since the nonlinearity was much more significant for the molybdenum samples, the figures in Table 3 would be in closer agreement if the nonlinear portion had been added to the charted strain distance ( $e_{cf}$ ) in the ductility equation (Equation 3.1).

## 2. Tensile Hysteresis Testing

Low strain cyclic tensile hysteresis loading tests were conducted on representative specimens from each heat treatment. Each sample was alternately loaded to and unloaded from 100, 250, 500, 750, and 1000 lbs in succession. Loading-unloading was continued in steps to 1500 and 2000 lbs until plastic deformation occurred. Once plastic deformation had commenced, the loading was continued until fracture. Distinct nonlinear "elastic" behavior was observed for both aluminum and molybdenum samples. Initially, these effects were suspected to be due to the imperfect stiffness and clearance in the specimen grips. In order to test this possibility, relatively larger steel samples were loaded and unloaded to 5000 lbs. In these a very minor degree of

nonlinearity was observed and it was determined that grip effects are saturated at a loading of only about 10 lbs (about 0.2 ksi stress). This could account for a portion of the low strain nonlinearity observed in the Fe-Cr-Al alloy samples, but for the Fe-Cr-Mo alloy samples, the behavior was much more complex.

For the Fe-Cr-Mo samples, the nonlinear region extends over a much wider range, corresponding to loads of about 75 lbs (stress of about 1.5 ksi). Roughly subtracting a proportion of this attributable to grip effects still leaves a significant degree of nonlinear response. In addition, all the Fe-Cr-Mo samples showed a sharp load drop followed by a gradual rise in this nonlinear elastic region. The load drop was repeated in subsequent loadings of a given sample. For this reason, and because the Fe-Cr-Al alloy samples did not display this load-drop phenomenon, it seems unlikely that this was due to the grips themselves (the grips are threaded). The load drop was observed only on loading, not on unloading.

The tensile hysteresis load-unload curves are presented in Figures 3.7-3.15. In these the vertical scale is in engineering stress (ksi) and the horizontal scale is relative strain ( $\times 10^{-3}$ ). The individual curves in the various load sequences are arbitrarily placed along this relative strain scale in order to provide a better means of comparison of the slope changes of the various curves. This

## FE-CR-MO HYSTERESIS

Figure 3.15 Fe-Cr-Mo Combined Tensile Hysteresis Tests

of course does not imply an actual strain offset between results from the various curves. However, on the plots where a set of variously heat-treated specimens are co-plotted, a direct strain comparison is possible for the curves which are originating from a common (relative) strain point. Once again, the points of origin (of the sets) were placed arbitrarily to separate the curves.

In interpreting the relative "resistance to strain" from these plots, we refer to the horizontal displacement of the near linear (near vertical) section from the point of origin, with higher "resistance to strain" corresponding to a smaller distance. Using that basis of comparison, the various samples have been ranked from higher relative resistance to lower relative resistance. These results are presented graphically in the figures and are summarized in Table 4.

Figures 3.7 to 3.15 also provide a comparison of the slopes of upper portions, showing that, in general the slope (modulus) increases with increasing stress.

Figures 3.16 to 3.336 were also derived from the tensile load-unload hysteresis tests. These figures have been contrived in order to provide a visual comparison of the slopes of the stress strain curves. Each line represents the slope of a tangent line to the stress strain curve near the maximum load point, indicated by the bold portion of the line. The bracketed, bold sections in these

plots represent the actual section of the stress strain curve which coincides with this tangent line. The vertical axis is engineering stress (ksi) and the horizontal scale is relative strain ( $\times 10^{-3}$ ).

It is important to note that what is being presented in these figures is the slope of the upper portion of the stress-strain curve only. The presentation should not be taken to mean that all the curves originated from the (relative) zero strain point. In addition, as presented earlier, all the curves were actually quite nonlinear at low stresses; a feature which has been omitted in the present figures.

It is significant to note the continuously increasing slopes (moduli) of both the loading and unloading curves, as the material apparently becomes more resistant to strain with increasing stress levels. In addition, typically there was a very rounded shoulder at the top of the unloading curve; this is represented in the presentation of Figures 3.16 to 3.36 by the distance between the highest represented stress-strain point (circle) and the upper limit of the bold, bracketed section of the tangent curve (the upper bracket). For clarity, the slopes of the loading curves are presented as solid lines; slopes of the unloading curves are presented as dashed lines.

### C. DAMPING CHARACTERISTICS

In his investigation of an Fe-Cr-Mo alloy, O'Toole [Ref. 6] reported a significant difference in the damping capacity of the 1000°C furnace cooled sample as compared to the other furnace cooled specimens (see Figure 3.37). Specifically, the 1000° sample required higher strain to activate the damping mechanism and the maximum specific damping capacity was significantly less.

To relate this to results of the present investigations, Figures 3.38 to 3.41 present the relationship of specific damping capacity (SDC) to average peak strain for the Fe-Cr-Al alloy, and Figure 3.42 is a composite of these. These results indicate no significant difference due to heat treatment temperature for furnace cooled Fe-Cr-Al alloy specimens. In fact, the 1000° curve is slightly displaced to the lower strains, an effect opposite to that reported by O'Toole for an Fe-Cr-Mo alloy at 1000°C heat treatment. In addition, the peak SDC is approximately the same as the other samples.

Results from the Fe-Cr-Mo alloy investigated here (which was not exactly the same ingot material as used by O'Toole) are presented in Figures 3.43 to 3.45, showing the relationship of SDC to average peak strain. These curves are combined in Figure 3.46. Consistent with O'Toole's results, the data for the alloy when heat treated at 1000°C

sample is displaced downward and to the right, corresponding to lower peak SDC, the peak occurring at a higher strain.

#### IV. CONCLUSIONS AND RECOMMENDATIONS

##### A. CONCLUSIONS

1. A phase change in the furnace cooled Fe-Cr-Mo alloy was not detected by dilatometric measurements.
2. It has been demonstrated that a pseudoelastic effect is present for all furnace cooled tensile samples. This effect was more pronounced for the Fe-Cr-Mo alloy than for the Fe-Cr-Al alloy.
3. During tensile hysteresis testing, increasing strain levels produced a corresponding increase in the apparent elastic modulus of the sample.
4. Both Fe-Cr-Al and Fe-Cr-Mo have high damping capacities under cyclic loading after being annealed and furnace cooled. This damping capacity is very strain dependent.
5. The somewhat lower level of damping capacity previously reported for a 1000°C furnace cooled Fe-Cr-Mo alloy was reconfirmed.

##### B. RECOMMENDATIONS

The following recommendations are proposed for further research and study on high damping Fe-Cr-Al and Fe-Cr-Mo alloys.

1. Further investigation of pseudoelastic effects, through low strain tension-compression testing, should be carried out.
2. Damping measurements should be taken over a wider temperature range, conforming to anticipated operating conditions.
3. The effects of damping at higher strains, higher strain rates, and for longer periods of time, should be studied.
4. Detailed microstructural analysis should be carried out via transmission electron microscopy.

5. The effects on damping capacity of various cooling rates should be studied further.
